We propose a dielectrophoresis model for phase-separated manganites. Without increase of the fraction of metallic phase, an insulator-metal transition occurs when a uniform electric field applied across the system exceeds a threshold value. Driven by the dielectrophoretic force, the metallic clusters reconfigure themselves into stripes along the direction of electric field, leading to the filamentous percolation. This process, which is time dependent, irreversible, and anisotropic, is a probable origin of the colossal electroresistance in manganites.

INTRODUCTION

Phase separation (PS) can be found in various condensed matter systems. In the past half a century, the effects of electric field on phase-separated liquids have been cross-fertilized by physicists, chemists, and biologists.1–5 Among them, a distinct phenomenon is dielectrophoresis:6 the mixing or demixing of neutral materials with different dielectric constants under a nonuniform electric field.2–5 It has also found wide application in microbiology, nanotechnology, polymer processing, etc.7,8 However, dielectrophoresis would seem unlikely in solids, which normally lack the necessary condition of flowability.

As for solids, PS has been demonstrated to be crucial to understanding various exotic phenomena in strongly correlated electronic materials,8 manganites being a typical example. In manganites, PS generally consists of ferromagnetic (FM) metallic phase and insulating phase which is usually antiferromagnetic and charge ordered (CO).9 One can understand the PS, as shown in Fig. 1, without external control, which is necessary for dielectrophoresis in liquids.7 Therefore, dielectrophoresis is not impossible in manganites although they are solids.

MODEL

As shown in Fig. 1, our model is based on a two-dimensional square lattice ($L \times L, L=64$) with a voltage drop $V$ applied in the $y$ direction. A fraction $p_M$ of the lattice sites are metallic, with the others insulating. The assumption of a fixed FM phase fraction will be checked behind. This binary mixture picture is adequate to describe the large scale PS consisting of FM and CO phases.9 A standard Metropolis algorithm is employed in our Monte Carlo simulation with the dielectrophoresis mechanism: exchange between nearest neighboring (NN) sites with the probability determined by the free energy change. Considering the free energy of electric field $F_E$ in the medium,3,4 the total free energy $F$ in our model can be written as

$$F = F_E + F_S = -\frac{1}{2} \int \varepsilon(r)E^2(r)\,dr + \oint AdS,$$

where $\varepsilon(r)$ denotes the dielectric constant and $E(r)$ is the local field at point $r$. $\varepsilon(r)$ equals $\varepsilon_M$ ($\varepsilon_i$) if the phase at $r$ is metallic (insulating). This anomalous CER calls for a further understanding of PS beyond the equilibrium ground state in manganites.

In this Brief Report, we propose a dielectrophoresis model to understand the PS dynamics associated with the CER in manganites. At the beginning, it is essential to demonstrate the possibility of dielectrophoresis in manganites being solid. Unlike liquid mixtures, the different phases in a prototype phase-separated manganite have the same chemical composition. The migration of $e^-$ electrons rather than cations makes the different phases in manganites “flowable” in a wide temperature range,14–16 satisfying the first condition of dielectrophoresis: ambulatory phases. The second condition, nonuniform electric field, can be solely self-generated by the PS, as shown in Fig. 1, without external control, which is necessary for dielectrophoresis in liquids.7 Therefore, dielectrophoresis is not impossible in manganites although they are solids.
metallic (insulating), where $e_M$ ($e_I$) is the dielectric constant of the metallic (insulating) phase. The second item in Eq. (1) plays the role of obstruction during dielectrophoresis. In real manganites, many factors can be obstruction in the transition between metastable states, e.g., domain interfaces, strains, and defects, and here we simplify the obstruction by characterizing them with the interface energy $F_I$ (Ref. 17) in Eq. (1). $F_I$ is proportional to the interface area $S$ between metallic and insulating regions with a coefficient $A$. Within the system, $E(r)$ is obtained using the resistor-network (RN) model. In the RN model, three types of resistors are distributed according to the links between NN sites: $R_M$ between metallic sites, $R_I$ between insulating sites, and $R_{MI}$ between a metallic and an insulating site, set as $(R_M+R_I)/2$ here. The voltage of each site $V(r)$ in the RN can be exactly solved by the Kirchhoff equations, as shown in Fig. 1.

Our simulation begins with a zero-field quench preprocess from a high temperature $T_0$ to $T_d$. Then, at $T_d$ fixed, the voltage $V$ changes between zero and a maximum value $V_m$, following an increasing-decreasing-increasing (IDI) path with a fixed rate [characterized by Monte Carlo steps (MCSs)]. Given the strong contrast between the electric properties of FM and CO phases, both the ratios $R_I/R_M$ and $e_M/e_I$ are quite large. Their values strongly depend on material, as well as doping and temperature. Experimentally, they can be determined by comparing the metal-rich limit and insulator-rich limit. To accelerate our simulation, a special case, $f=R_I/R_M=e_M/e_I$ ($f \gg 1$), will be used. More general cases without such restriction have also been tested. It is found that the physical picture is unaffected as long as $f \gg 1$. The values of parameters used in our simulations are listed in Table I, if not noted explicitly.

**RESULTS**

The resistance $R_y$ along the direction of the electric field is shown in Fig. 2 as a function of the external electric field $E = V/(L-1)$. Initially, the resistance is only weakly dependent on $E$. Then, the CER transition takes place once $E$ exceeds a threshold $E_c$. In the subsequent stages of increasing-decreasing $E$, $R_y$ remains low and nonlinear even for $E$ well below $E_c$. We find that the value of $E_c$ increases with the IDI rate (not shown here), in agreement with the observations in $La_{0.225}Pr_{0.4}Ca_{0.375}MnO_3$, implying that the process is a relaxative evolution between metastable states. We use the ratio $\delta_{ER} = R_{y\text{max}}/R_{y\text{min}}$ to characterize the CER,

![FIG. 2. (Color online) Resistances as a function of the applied field. Inset: $\delta_{ER}$ as a function of $f$.](image)

where $R_{y\text{max}}(R_{y\text{min}})$ is the maximum (minimum) of $R_y$ before (after) the CER transition. $\delta_{ER}$ appears to be proportional to $f$, as shown in the inset of Fig. 2.

To understand the above transport behavior, four snapshots of PS pattern taken at different stages during the IDI process are shown in Fig. 3. Before $E$ exceeds $E_c$, as shown in Fig. 3(a), the metallic sites accumulate into clusters in favor of lower interface energy. However, once $E > E_c$, the energy gained from dielectrophoresis overcomes the interface energy barrier, and the PS structure is rapidly reconfigured into a stripelike pattern, as shown in Fig. 3(b). As a result of the percolation, the system has higher overall conductance and higher effective dielectric constant. Upon further increasing the field, the percolation path is strengthened, as shown in Fig. 3(c), giving rise to a slight decrease of resistance. When the field is decreasing, the percolation path is hardly destroyed except when $E$ is close to zero. When $E$ is too small to compete against the surface tension and thermal energy, the percolation path will be corroded gradually and, given enough time, eventually break down, as shown in Fig. 3(d). Nevertheless, with the parameters as listed in Table I, the main shape of percolation path can remain effective for a finite period of time, which accounts for the nonlinear transport behavior observed in Fig. 2 after the voltage threshold is first exceeded. As a result, the dielectrophoresis in our simulation is irreversible.

![FIG. 3. (Color online) Four snapshots taken from an evolution cycle of dielectrophoresis.](image)
FIG. 4. (Color online) The field threshold as a function of the temperature. Here, the surface tension coefficient $A$ is chosen as the unit, while the other parameters have the values in Table I.

Besides the changing rate of the electric field, the interface energy coefficient $A$ and temperature also play important roles in modulating the dielectrophoresis. In our simulation, the dependence of $(E_c/A)$ upon $(T_d/A)$ is quite nontrivial, as shown in Fig. 4. $(E_c/A)$ reaches the minimum at $(T_d/A) \sim 1.1$. It agrees with the experimental evidences that there is a $T$ window for the dynamic PS ($T \sim 25–85$ K) (Ref. 15) or a novel consolute critical point $T \sim 30$ K (Ref. 13) in the phase-separated L$_{bt2}$Pr$_{0.4}$Ca$_{0.6}$MnO$_3$. The origin could be that, at large $(T_d/A)$, the thermal energy can destroy a stable percolation type PS in manganites would generate inhomogeneous transport anisotropy. In our simulation, resistances both parallel and perpendicular to the electric field are drastically reduced, a simulation, the dependence of $R_x$ upon $dRx$ is chosen as the unit, while the other parameters have the values in Table I.

As stated above, the obstruction is responsible for the process-dependent conductance behavior and novel critical point. Although the parameter $A$ cannot be directly measured in experiments, the consolute critical point does provide a way to compare our result of $E_c$ with experimental results. Using the parameters values taken from experiments, $E_c$ in our model is estimated to be $\sim 10^3$ V/m, within the same order of magnitude of the experimental data. As we compare the physics of the present filamentous percolation picture and the CO-FM collapse picture, one notable thing is that $E_c$ required for the CO-FM collapse is indeed much larger than $E_c$ in our model. The reason is that the CER here is induced by merely repatterning of the CO and FM phases, not by converting them to another phases, which costs more energy to compensate for the energy difference between CO and FM phases. Therefore, the assumption of the fixed FM phase fraction in our model is self-satisfied for the low electric field case. Moreover, even if there does exist a possible slight increase $[<1\%]$ of FM phase fraction, the dielectrophoresis remains the most probable contribution to the CER effect, since the CER is not very sensitive to the FM fraction.

Since the metallic filaments along the direction of electric field break the space symmetry of PS, it is natural to expect transport anisotropy. In our simulation, resistances both along $(R_x)$ and across $(R_y)$ the electric field are affected, as shown in Fig. 5. Before the voltage first reaches the threshold, the transport is isotropic, and resistances along both $x$ and $y$ are highly independent of the voltage drop. At the voltage threshold, the CER transition is accompanied by the sharp emergence of transport anisotropy. While $R_y$ along the direction of the electric field is drastically reduced, a simultaneous increase of $R_x$ across the electric field occurs reversibly near the threshold voltage. Furthermore, the system has the intriguing feature that it is metallic $((dR_x/dT.ini))$ along the electric field direction but insulating $((dR_y/dT.ini))$ in the perpendicular direction.

DISCUSSION

Using the Bruggeman-Landauer (BL) equation based on self-consistent effective medium approximation, the effective conductance of a well-distributed and isotropic binary mixture can be estimated as

$$C = \frac{1}{2(d-1)} \left[ -P + \sqrt{P^2 + 4(d-1)C_fC_M} \right],$$

where $d$ is the dimensionality and $C_f=1/R_f$ ($C_M=1/R_M$) is the conductance of insulating (metallic) phases; $P=C_M(1-dp_M)+C_f(dp_M+1-d)$. Since $C_f/C_M \sim 0$, Eq. (2) can be simplified to $C \approx C_f/(1-dp_M)$ for all cases ($f \gg 1$) in our model. Therefore, the effective resistance is about $(1-dp_M)R_f=0.6R_f$ for all values of $f$ considered here, and the conductance is isotropic. In our simulation, the conductance is isotropic and its value is indeed independent of $f$ before the CER transition. The value of $R_x=0.55R_f$ is close to, but slightly smaller than, the BL estimation. The reason is that the accumulation of metallic phases into clusters will enhance the conductance. As the percolation path is formed, $R_x^{\text{min}}$ can be estimated as $R_f/(p_M+1-p_M)=R_f/(p_M)$ since $f \gg 1$. It accounts for the linear dependence of $\delta_{EB}$ on $f$, as shown in the inset of Fig. 2. (The relationship $\delta_{EB} \approx R_f/R_y$ is independent of the choice of $e_M/e_f$ in our model.) On the other hand, $R_x^{\max}$ after the CER transition is approximately $R_f(1-p_M)+R_M p_M = R_f(1-2p_M)$. Compared with its original value, there is a relative small change (increase) of $R_x$: $R_x^{\max}/R_x^{\text{min}}=(1-p_M)/(1-2p_M)$ by the two-dimensional BL equation.

Compared with the dielectrophoresis in liquids, there are two remarkable features in phase-separated manganites, adding to its appeal to the research community. Firstly, the prototype PS in manganites would generate inhomogeneous
electric field by itself, while for liquids, great effort was made to artificially produce nonuniform electric field.\textsuperscript{4,7} Yet, as in the cases of the liquids, the PS in manganites can also be controlled by applying artificially nonuniform electric field (e.g., patterning of gates), offering great potential for making devices. Secondly, the diversity of electric properties between different phases in manganites, e.g., resistance and dielectric constant, is far greater than those in consolute liquids. In real manganites, the colossal electroresistance and/or magnetoresistance implies a colossal difference between the resistivities of metallic and insulating phases. Therefore, the main difficulties of dielectrophoresis in liquid, i.e., a large voltage required and weak effects, could be overcome in manganites.

In conclusion, we introduced the dielectrophoresis dynamics, a phenomenon usually existing in mixed phase liquids, to investigate the phase separation in solid manganites. We have shown that the colossal electroresistance could be achieved by the filamentous percolation through a dielectrophoresis dynamic process without increasing the metallic composition. Our results give a probable explanation of the colossal electroresistance in manganites, including its time dependence, irreversibility, and the consolute critical point. Besides, it was also predicted that the dielectrophoresis process renders the system anisotropic. All these properties cannot be explained by the physics of single phases but arise from phase competition. The present work also highlights the analogy\textsuperscript{8} between strongly correlated electronic systems and complex systems in the classical world, e.g., complex fluids.
